Psychosocial risk factors for coronary heart disease (CHD)
Psychosocial risk factors for CHD

A consensus statement from the National Heart Foundation of Australia

Psychosocial risk factors for CHD

• An update on evidence regarding psychosocial risk factors for CHD:
  – chronic stressors (in particular, work stress)
  – acute individual stressors
  – acute population stressors.¹

• Provides guidance for health professionals in acute and primary care.¹

• Complements a separate updated statement on depression and CHD (published May 2013).²

References
Chronic stressors

• Work stress:
  – job strain
  – effort–reward imbalance
  – organisational injustice
  – shift work
  – other types of work stress
  – work stress and prognosis of CHD.

• Social isolation and social support.
Work stress

- Perceived chronic job strain and shift work are associated with a small absolute increased risk of developing CHD, but there is limited evidence regarding their effect on the prognosis of CHD.
Job strain

- Job strain as a risk factor for CHD is much lower than that for standard CHD risks, such as smoking or hypertension.
- The Whitehall II study demonstrated that adding information on job strain does not improve 10-year risk prediction for CHD above the standard Framingham risk score.¹

Reference
Shift work

- Associated with a moderate increase in myocardial infarction (MI) (RR, 1.23; 95% CI, 1.15–1.31) and CHD events (RR, 1.24; 95% CI, 1.10–1.39), but not with increased rates of mortality.
- All shift work schedules studied, with the exception of evening shifts, were associated with a higher risk of CHD events, even after adjusting for unhealthy behaviour and other CHD risks.

Reference
Work stress

- Evidence regarding a relationship between CHD and job (in)security, job satisfaction, working hours, effort-reward imbalance and job loss is inconclusive.
Work stress

- Workplace programs aimed at weight loss, exercise and other standard cardiovascular risk factors may have positive outcomes for these risk factors, but no evidence is available regarding the effect of such programs on the development of CHD.
Social isolation

- Social isolation after MI is associated with an adverse prognosis.
- Although measures to reduce social isolation are likely to produce positive psychosocial effects, it is unclear whether this would also improve CHD outcomes.
Acute stressors

• Individual stressors include:
  – acute emotional responses
  – bereavement
  – acute work related stressors and job loss.

• Population stressors include:
  – natural and unnatural disasters
  – sporting events.

• Takotsubo cardiomyopathy
Acute emotional stress

- Acute emotional stress may trigger MI or takotsubo (‘stress’) cardiomyopathy, but the absolute increase in transient risk from an individual stressor is low.
Population stressors

- Awareness of the potential for increased cardiovascular risk among populations exposed to natural disasters and other conditions of extreme stress may be useful for emergency services response planning.

Reference
Recommendation

In recognition that acute stressors can trigger CHD events, wider public access to defibrillators should be available where large populations gather, such as sporting venues, and as part of the response to natural and other disasters.

Reference
• Psychosocial stressors have an impact on CHD, but clinical significance and prevention require further study.
